--	--

The measuring equipment needed is a measuring tape to measure the distance of the ramp. A stopwatch is used to measure the time taken for the block to slide down the ramp. Ramps ~~are~~ ^{of} different materials are used like of metal, rubber, wood, etc. The independent variable is the type of surface material of the ramp. The dependent variable is the average speed of the block ~~at~~ sliding down the ramp. Control variables are the surface area of the ramp, the height of the ramp, the surface material, ~~and~~ ^{size} ~~volume~~ of block, ~~no cross wind, and~~ ^{no cross wind, and} that the block is released from rest.

The average speed of the block is determined by applying the equation: $\text{average speed} = \frac{\text{total distance}}{\text{total time taken}}$

The surface material of a ramp affects the speed sliding down and it's called friction. If we don't want the speed sliding down to be affected, the ramp should be smooth. The measuring equipments are stop watch and ruler. The average speed will be determined by ~~comp~~ comparing it with a non smooth surface and ~~a~~ smooth surface.

Take a block, ~~the~~ it should be of same material each time. The height 'h' should be constant throughout the experiment. ^{these are the controls.} The independent variable is the surface material of a ramp. The dependant variable is the ^{average} speed of the block sliding down the ramp. Measure the length of ^{using measuring tape} the ramp and record it. For change the surface by either using a smooth surface or placing sand paper. For every different surface the time taken to reach the end should be recorded using a stopwatch. start the stopwatch ~~and~~ when the block starts sliding down ramp and stop it when the block reaches the end of the ramp. The average speed can be found using the equation ;

$$\text{average speed} = \frac{\text{distance}}{\text{time taken}}$$

substitute values in the equation and find the average speed on different surfaces of the ramp.
